We show that optically encoded two-qubit Bell states can be unambiguously discriminated with a success probability of more than 50% in both single-rail and dual-rail encodings by using active linear-optical resources that include Gaussian squeezing operations. These results are in contrast to the well-known upper bound of 50% for unambiguous discrimination of dual-rail Bell states using passive, static linear optics and arbitrarily many vacuum modes. We present experimentally feasible schemes that improve the success probability to 64.3% in dual-rail and to 62.5% in single-rail for a uniform random distribution of Bell states. Conceptually, this demonstrates that neither interactions that induce nonlinear mode transformations (such as Kerr interactions) nor auxiliary entangled photons are required to go beyond the one-half limit. We discuss the optimality of our single-rail scheme, and talk about an application of our dual-rail scheme in quantum communication.

PACS numbers: 03.67.Hk, 42.50.Ex

Introduction— Bell measurements, jointly projecting two qubits onto the so-called Bell basis, constitute a crucial step in many quantum computation and communication protocols, including dense coding [1], quantum repeaters [2], and teleportation-based quantum computation [3, 4]. The two most common encodings for optical Bell states are the single-rail (SR) and the dual-rail (DR) encodings [5]. An important result with regards to Bell measurements (BMs) is the impossibility of deterministic unambiguous DR BMs using passive linear optics [6], even when arbitrarily many auxiliary photons, photon-number-resolving detectors (PNRDs), and dynamical (conditionally changing) networks are available [7]. Quantitatively, the success probability for unambiguous DR BMs using a static linear network aided by vacuum modes and PNRDs was shown to be tightly bounded from above by 50% [8]. In the supplementary section of this work, we give a simple proof showing that the upper bound of 50% also holds for SR BMs, even with the inclusion of dynamical networks [21]. A fully deterministic BM requires at least a cubic Hamiltonian [22] (which is highly inefficient in practice [9]), unless one relies on embedded Bell-state analysis [10]. Current proposals for going past the 50% upper bound without using experimentally challenging nonlinearities rely on using entangled photon ancilla states (which are generally expensive and probabilistic to create) and a sufficiently large interferometer to combine the signal and ancilla modes [11], [23]. Similar to Ref. [4], BMs in these proposals are made near-deterministic in the limit of asymptotically large ancilla states, but without the need for conditional dynamics.

In light of the above facts, the motivation for this work is threefold. First, from a theoretical point of view, while an upper bound on the success probability of unambiguous Bell discrimination using *passive* linear optics

and auxiliary vacuum modes has been established and well celebrated, no such upper bound has been shown to exist for *active* linear-optical circuits that include additional single-mode squeezers and correspond to arbitrary quadratic Hamiltonians [12] (and hence arbitrary linear transformations of the mode operators [24]). Even though there is a renewed interest in the area of BMs [11, 13], there exists a gap in our understanding of what is possible between passive linear optics and cubic nonlinearities [25]. Second, historically, squeezing has typically been used in *continuous-variable* quantum computing and information processing [12, 14]. We, however, want to explore the use of squeezing in *discrete-variable* BMs, opening up the possibility of combining continuous-variable and discrete-variable toolkits for enhanced quantum information processing [5]. Finally, from an experimental point of view, squeezing low-photon-number states has become an achievable feat in the last few years [15], which warrants an exploration into its potential for quantum information processing. Note that in Ref. [15], optical squeezing has been promoted from an offline experimental resource to a controllable online operation, just as is needed for our purposes.

We show in this paper that beating the 50% bound on the success probability of unambiguous BM is possible by using single-mode squeezers and beam splitters. Our schemes are free of ancilla photons and vacuum modes. Hence, the static interferometric networks needed are no larger than the signal-mode space (i.e., four modes in DR and two modes in SR). We first present a scheme with a success probability of 64.3% for DR unambiguous BM (while we do not know if this is optimal). We then consider SR BMs using an arbitrary two-mode network of beam splitters and squeezers characterized by real parameters. We show that for equal squeezing in the two modes, there exists an entire class of interferometers that

yield 62.5% success probability. We then look at experimental considerations and possible applications of our schemes. In the supplementary section, we discuss numerical results that show that it is not possible to beat 62.5% with a real two-mode active linear network (i.e., without phase shifts) for a squeezing of up to 8.686 dB.

Dual-Rail Bell Discrimination— Let us start with DR Bell states in polarization basis, given by

$$|\psi^\pm\rangle = \frac{1}{\sqrt{2}} (|HV\rangle \pm |VH\rangle), \quad (1a)$$

$$|\phi^\pm\rangle = \frac{1}{\sqrt{2}} (|HH\rangle \pm |VV\rangle), \quad (1b)$$

where H and V stand for horizontal and vertical polarizations, respectively. Consider the setup shown in Fig. [1] with Bell states as the input. We choose a balanced

FIG. 1: Scheme for DR Bell discrimination that yields a success probability of 64.2%. The Bell states pass through a balanced beam splitter ($\mathcal{B}$), two polarizing beam splitters ($\mathcal{P}_1$ and $\mathcal{P}_2$), and four squeezers ($\mathcal{S}_1$ to $\mathcal{S}_4$) with a squeezing of 5.7195 dB each. The output is sent to PNRDs.

beam splitter whose action on the mode operator vector $(a_1^\dagger \ a_2^\dagger)^T$ is represented by the matrix $\frac{1}{\sqrt{2}} \begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix}$. After passing through the beam splitter and the polarizing beam splitters (where vertically polarized photons are reflected), the Bell states transform into

$$|\psi^+\rangle \rightarrow \frac{i}{\sqrt{2}} (|1100\rangle + |0011\rangle), \quad (2a)$$

$$|\psi^-\rangle \rightarrow \frac{1}{\sqrt{2}} (|1010\rangle - |0101\rangle), \quad (2b)$$

$$|\phi^\pm\rangle \rightarrow \frac{i}{2} (|2000\rangle + |0002\rangle \pm |0200\rangle \pm |0020\rangle). \quad (2c)$$

We will disregard global phases from now on. Notice that at this point the states $|\psi^\pm\rangle$ would be perfectly distinguishable if we were to detect four-mode photon-number patterns, while the states $|\phi^\pm\rangle$ would be indistinguishable. Single-mode squeezers add photons in pairs, thereby preserving the even and odd parity of the number of photons in each output mode. Hence, the states $|\psi^\pm\rangle$ remain perfectly distinguishable after applying squeezing. For this reason, we only concern ourselves with the states $|\phi^\pm\rangle$ in the following analysis.

Now consider the squeezing operator $\mathcal{S}$ given by $\exp[r(a^2 - a^{\dagger 2})/2]$. After normal ordering, we can write its effect on the relevant Fock states $|0\rangle$, $|1\rangle$, and $|2\rangle$ as

$$\mathcal{S}|0\rangle = \sqrt{\text{sech } r} \exp(-\tanh r a^{\dagger 2}/2) |0\rangle, \quad (3a)$$

$$\mathcal{S}|1\rangle = (\text{sech } r)^{3/2} \exp(-\tanh r a^{\dagger 2}/2) |1\rangle, \quad (3b)$$

$$\mathcal{S}|2\rangle = \sqrt{\text{sech } r/2} \tanh r \exp(-\tanh r a^{\dagger 2}/2) |0\rangle + (\text{sech } r)^{5/2} \exp(-\tanh r a^{\dagger 2}/2) |2\rangle. \quad (3c)$$

Each Bell state is transformed into an infinite sum of photonic four-mode states when it is passed through the squeezers. After some algebra, we can identify the coefficients for the different photonic states (the coefficients for the states $|2000\rangle$, $|4246\rangle$, etc.). One possible strategy for unambiguous discrimination, then, relies on choosing a squeezing value where some of these coefficients are zero for $|\phi^+\rangle$, but non-zero for $|\phi^-\rangle$, so that some outputs occur unambiguously for $|\phi^-\rangle$. Eq. (4) below shows the output from the squeezers up to two-photon terms:

$$|\phi^\pm\rangle \rightarrow \frac{\alpha^\pm}{\sqrt{2}} |0000\rangle - \frac{1}{2} (\tanh r \alpha^\pm - \text{sech}^4 r) (|2000\rangle + |0002\rangle) - \frac{1}{2} (\tanh r \alpha^\pm \mp \text{sech}^4 r) (|0200\rangle + |0020\rangle), \quad (4)$$

where $\alpha^\pm = \tanh r \text{sech}^2 r (1 \pm 1)$. The complete output is presented in the supplementary section, but we can already see that the vacuum output is unique to the input $|\phi^+\rangle$, leading to an above-50% success probability of BM for any non-zero value of squeezing. By picking $r = 0.6585$ (a squeezing of 5.7195 dB [26]), so that $\tanh r \alpha^+ - \text{sech}^4 r = 0$, we can make all the two-photon output terms unique to $|\phi^-\rangle$. At this value, the vacuum coefficient in $|\phi^+\rangle$ is also at its maximum. Hence, the most significant unambiguous output terms for our input Bell states $|\phi^\pm\rangle$ (denoted by $|\phi^\pm\rangle_{\text{unique}}$) are given by:

$$\begin{aligned} |\phi^+\rangle_{\text{unique}} &\sim +0.5443 |0000\rangle, \\ |\phi^-\rangle_{\text{unique}} &\sim +0.2222 |2000\rangle - 0.2222 |0200\rangle \\ &\quad - 0.2222 |0020\rangle + 0.2222 |0002\rangle. \end{aligned} \quad (5)$$

As a by-product of the above condition, a number of higher-photon-number terms also become unambiguous (i.e., only show up for $|\phi^+\rangle$). Adding up the success probabilities from these higher-order terms, we obtain a total probability of 37.48% and 19.75% for the inputs $|\phi^+\rangle$ and $|\phi^-\rangle$, respectively. Combining this with deterministic discrimination of $|\psi^\pm\rangle$, and assuming equal input probability for each of the Bell states, the network shown in Fig. [1] yields an overall success probability of 64.3%.

Single-Rail Bell Discrimination— In SR, similar to the DR case, a scheme relying on a balanced beam splitter followed by two single-mode squeezers, each with a

squeezing of 6.2696 dB ($r = 0.7218$) produces a success probability of 62.5%. However, here we shall consider a more general setup: a two-mode linear circuit parametrized by real reflectivity and squeezing parameters. The equal-squeezing scheme is later discussed as a special case of this general setup.

Bell states in SR are given by:

$$|\psi^\pm\rangle = \frac{1}{\sqrt{2}}(|10\rangle \pm |01\rangle), \quad (6a)$$

$$|\phi^\pm\rangle = \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle). \quad (6b)$$

Using the Bloch-Messiah reduction [16], an arbitrary two-mode squeezing network can be decomposed into a combination of beam splitters and single-mode squeezers, as shown in Fig. [2]. The effect of the first beam splitter B_1

FIG. 2: In SR, we consider the Bloch-Messiah reduction of a general two-mode squeezing network. The Bell states are passed through a beam splitter $B_1(\theta_1)$, followed by squeezers $S_1(r_1)$ and $S_2(r_2)$, and finally through a second beam splitter $B_2(\theta_2)$; θ_1 and θ_2 are the reflectivity parameters, and r_1 and r_2 are the squeezing parameters. The output is sent to PNRDs. We only discuss networks with real parameters.

on the operator vector $(a_1^\dagger \ a_2^\dagger)^T$ is given by the matrix $\begin{pmatrix} \cos \theta_1 & \sin \theta_1 \\ -\sin \theta_1 & \cos \theta_1 \end{pmatrix}$, and that of the second beam splitter is given by the substitution $\theta_1 \rightarrow \theta_2$. Applying the beam splitters and squeezers sequentially on the input Bell states, the states $|\psi^\pm\rangle$ are transformed into:

$$|\psi^\pm\rangle \rightarrow \sqrt{\frac{\text{sech } r_1 \text{sech } r_2}{2}} \exp(x a_1^{\dagger 2} + y a_2^{\dagger 2} + z a_1^\dagger a_2^\dagger) \times (\Omega^\pm |10\rangle + \omega^\pm |01\rangle), \quad (7)$$

where $x = -\tanh r_1 \cos^2 \theta_2/2 - \tanh r_2 \sin^2 \theta_2/2$, $y = -\tanh r_1 \sin^2 \theta_2/2 - \tanh r_2 \cos^2 \theta_2/2$, $z = \cos \theta_2 \sin \theta_2 (-\tanh r_1 + \tanh r_2)$, and

$$\Omega^\pm = \text{sech } r_1 \cos \theta_2 (\cos \theta_1 \mp \sin \theta_1) - \text{sech } r_2 \sin \theta_2 (\sin \theta_1 \pm \cos \theta_1), \quad (8a)$$

$$\omega^\pm = \text{sech } r_1 \sin \theta_2 (\cos \theta_1 \mp \sin \theta_1) + \text{sech } r_2 \cos \theta_2 (\sin \theta_1 \pm \cos \theta_1). \quad (8b)$$

The case of passive linear optics is obtained by setting $r = 0$. Specifically, $|\psi^+\rangle \rightarrow |01\rangle$ and $|\psi^-\rangle \rightarrow |10\rangle$ can be recovered by suitably choosing θ_1 and θ_2 , e.g., $\theta_1 = 0$ and $\theta_2 = \pi/4$. By writing out the first few terms in Eq.

(7), it can be seen that for an apparatus that measures photon numbers in each mode, at least one of the four conditions ($\Omega^+ = 0$, $\Omega^- = 0$, $\omega^+ = 0$ or $\omega^- = 0$) must be satisfied to unambiguously discriminate between $|\psi^\pm\rangle$ with a non-zero probability. If we choose to ignore the above constraints, we may distinguish the states $|\phi^\pm\rangle$ at most deterministically, but that will yield an overall success probability of 50%, which is no better than that achieved with a passive linear network. Hence, satisfying one of these conditions is necessary to go beyond the passive linear upper bound of 50%.

We now look at the output for the states $|\phi^\pm\rangle$:

$$|\phi^\pm\rangle \rightarrow \sqrt{\frac{\text{sech } r_1 \text{sech } r_2}{2}} \exp(x a_1^{\dagger 2} + y a_2^{\dagger 2} + z a_1^\dagger a_2^\dagger) \times (\gamma^\pm |00\rangle + \rho^\pm |02\rangle - \rho^\pm |20\rangle + \zeta^\pm |11\rangle), \quad (9)$$

where

$$\gamma^\pm = 1 \mp \sin 2\theta_1 (\tanh r_1 - \tanh r_2)/2, \quad (10a)$$

$$\rho^\pm = \pm 1/\sqrt{2} (\cos 2\theta_1 \sin 2\theta_2 \text{sech } r_1 \text{sech } r_2 - \sin 2\theta_1 (\sin^2 \theta_2 \text{sech}^2 r_1 - \cos^2 \theta_2 \text{sech}^2 r_2)), \quad (10b)$$

$$\zeta^\pm = \pm \cos 2\theta_1 \cos 2\theta_2 \text{sech } r_1 \text{sech } r_2 \mp \sin 2\theta_1 \sin 2\theta_2 (\text{sech}^2 r_1 + \text{sech}^2 r_2)/2. \quad (10c)$$

Eqs. (7) and (9) show that $|\psi^\pm\rangle$ always result in an odd number of photons in the output, while $|\phi^\pm\rangle$ result in an even number. Hence, we only have to distinguish $|\psi^+\rangle$ from $|\psi^-\rangle$, and $|\phi^+\rangle$ from $|\phi^-\rangle$. Eqs. (7) and (9) allow us to numerically analyze the case of a general two-mode network in the supplementary section. In the following, we analytically consider the case of equal squeezing ($r_1 = r_2$), for which we achieve a success probability of 62.5%.

Single-Rail, Equal Squeezing— For $r_1 = r_2 = r$, $\Omega^+ = 0 \Rightarrow \omega^- = 0$, and $\Omega^- = 0 \Rightarrow \omega^+ = 0$, as can be seen from Eq. (8). Hence, imposing any of the four conditions renders the states $|\psi^\pm\rangle$ completely distinguishable, as evident from Eq. (7). Further, we only need to look at the constraints $\Omega^\pm = 0$ to infer the success probabilities for $\omega^\pm = 0$. From Eqs. (8) and (10), we have

$$\Omega^\pm = 0 \Rightarrow \begin{cases} \cos^2 \theta_2 = (1 \pm \sin 2\theta_1)/2, \\ \rho^+ = \pm \text{sech}^2 r / \sqrt{2}, \ \zeta^+ = 0, \\ \rho^- = \mp \text{sech}^2 r / \sqrt{2}, \ \zeta^- = 0. \end{cases} \quad (11)$$

Combined with $x = y = -\tanh r/2$, $z = 0$, and $\gamma^\pm = 1$, we see that after imposing $\Omega^\pm = 0$ the coefficients for $|\phi^\pm\rangle$ are independent of θ_1 and θ_2 . This implies that each value of r gives an entire class of networks with the same unambiguous-discrimination success probability. For example, a network with a balanced beam splitter after equal-strength squeezers gives the same success probability as the one with the order reversed. Further,

setting $r = 0$ gives us an entire class of passive networks for which $|\psi^\pm\rangle$ are distinguishable and $|\phi^\pm\rangle$ are indistinguishable. As a final observation, since $\Omega^+ = 0$ and $\Omega^- = 0$ give only an immaterial sign difference in $\rho^\pm$, we are free to choose either condition for determining the success probability. In the following, we have chosen $\Omega^+ = 0$.

We can now evaluate Eq. (9) with the above simplifications to write the output $|\phi^\pm\rangle$ analytically in Fock space. The complete output is presented in the supplementary section, but the following truncated form highlights the main aspects of the calculation (similar to the DR case):

$$|\phi^\pm\rangle \rightarrow \frac{\text{sech } r}{\sqrt{2}} |00\rangle + \frac{\text{sech } r}{2} (-\tanh r \mp \text{sech}^2 r) |20\rangle + \frac{\text{sech } r}{2} (-\tanh r \pm \text{sech}^2 r) |02\rangle + \dots, \quad (12)$$

where we have only kept terms up to two photons. While the vacuum output is always ambiguous, the states $|20\rangle$ and $|02\rangle$ can be made unambiguous at $r = 0.7218$ (a squeezing of 6.2696 dB). Adding up the success probabilities from higher-order unambiguous terms yields a success probability of 25.03% for each of the states $|\phi^\pm\rangle$, resulting in an overall probability of 62.5%. We find numerically that for a phase-free and at most 8.686 dB squeezed, but otherwise arbitrary, two-mode squeezing network, 62.5% is indeed the best efficiency (discussion given in the supplementary part).

Experimental Success Probabilities— To take into account the experimental upper limit on the photon-number resolution of the PNRDs, we calculated *effective* success probabilities for equal-squeezing schemes considering PNRD resolutions of 2, 5, and 10 photons (while still assuming unit detection efficiency). Table [I] shows that almost all the benefits of the presented schemes can be harnessed with PNRDs that can resolve up to 10 photons [27], which may be possible with current technology [17, 18].

TABLE I: Experimental Success Probabilities

Encoding	PNRD	Success
	Upper Limit	Probability
Dual-Rail	2 Photons	26.5%
	5 Photons	56.1%
	10 Photons	63.2%
Single-Rail	2 Photons	41.8%
	5 Photons	56.3%
	10 Photons	62.0%

A further important experimental consideration is whether, and to what extent, our schemes are robust against photon losses (for example, through an inefficient detector). The SR scheme, as in the passive case, is not

robust in this regard. But, note that in DR a passive linear setup could detect single-photon losses. Remarkably, our squeezing-enhanced DR scheme achieves the same. To see this, recall Eqs. (2) and the fact that squeezing adds photons in pairs. Hence, after the four single-mode squeezers, the Bell states have the form

$$\begin{aligned} |\psi^+\rangle &\rightarrow \sim |odd, odd, even, even\rangle + |even, even, odd, odd\rangle, \\ |\psi^-\rangle &\rightarrow \sim |odd, even, odd, even\rangle - |even, odd, even, odd\rangle, \\ |\phi^\pm\rangle &\rightarrow \sim |even, even, even, even\rangle, \end{aligned}$$

where we have only shown the even/odd number of the photons in each output mode. The above equation shows that *measuring an even number of photons in an odd number of output modes signals a single-photon loss*. Such a measurement can be discarded, leading to a reduced success probability depending on the single-photon loss rate in the experimental setup. In contrast to the passive linear-optical case, two-photon losses cannot be reliably identified.

Applications— Efficient BMs have direct applications in quantum computation and communication. Whereas measurement-based quantum computation requires at least near-deterministic teleportation steps [3, 4], probabilistic BMs may be used in conjunction with local quantum memories for connecting the elementary segments of a quantum repeater [19]. Such a probabilistic setup is sufficient to suppress the exponential decay of entanglement due to channel transmission losses. The pair-creation rates in a general repeater chain of total length L are proportional to $(L/L_0)^{\log_2(2P_{\text{swap}}/3)}$, with repeater stations separated by distances L_0 , and the success probability for entanglement swapping given by P_{swap} . P_{swap} effectively corresponds to the BM efficiency. This rate formula is a good approximation for small initial distribution efficiencies over L_0 and perfect quantum memories [19]. For a typical repeater example of $L = 5120$ km with $L_0 = 20$ km, we have $L/L_0 = 256$. This leads to rates of ~ 0.000152 using optimal, passive BMs, while our local-squeezing-enhanced DR scheme (with four squeezers at each repeater station) will ideally give ~ 0.001140 . Thus, in this example, we obtain an improvement of almost one order of magnitude, reducing the number of repeater chains operating in parallel from 10,000 to 1,000 for the distribution of at least one long-distance entangled pair per unit time.

Summary and Outlook— We have presented experimentally feasible schemes relying on static, active linear optics that increase the success probability of optical qubit BMs beyond 50% without introducing any form of ancilla states. Our results open up interesting possibilities for the use of squeezing in discrete-variable quantum information processing. It remains to be seen whether the addition of vacuum modes to our schemes increases the success probability further, possibly to near 100%.

Acknowledgements— We thank T. Ralph, A. Furusawa, and T. Rudolph for helpful input and discussions. H.Z. also enjoyed talking to C. Cafaro, R. Wickert, and V. Vaibhav about various related questions, and acknowledges support from the Emmy Noether program of the DFG.

- [21] Converting between SR and DR encodings requires non-linear optics, which means that there is no intuitive way of inferring the success probability in SR given that in DR, and vice versa. Hence, throughout this paper, we treat DR and SR encodings separately.
- [22] With regards to the possibility of a deterministic BM with the help of arbitrary quadratic Hamiltonians together with PNRDs, auxiliary photons, and conditional dynamics, no-go theorems can be derived for both SR and DR encodings by extending the formalism presented in [20] to the case of arbitrary linear transformations including squeezing. The relevant calculations have been omitted in the interest of space, but are a straightforward extension of the formalism of Ref. [20].
- [23] Technically, the scheme given in Ref. [11] is for DR, but an extension of this scheme also works in SR, and will be given elsewhere.
- [24] As mentioned earlier, we only know that a fully deterministic BM requires at least a cubic Hamiltonian.
- [25] Ref. [13], which claimed to show near-deterministic BMs (with an arbitrarily small ambiguity) in DR by using passive linear optics and vacuum modes, was later retracted because of erroneous results.
- [26] The conversion from the unitless parameter r to squeezing in dB is $-10 \log_{10}(\exp(-2r))$.
- [27] Notice that for a resolution of up to 2 photons, the success probability goes below 50%, which is worse than the passive linear case. The states $|\psi^\pm\rangle$ produce outputs that have at most one photon in a mode in the case of passive linear optics, whereas in our schemes, $|\psi^\pm\rangle$ produce a significant number of outputs that have more than two photons in a mode due to squeezing. Ignoring these higher-photon-number terms leads to a reduced success probability.

SUPPLEMENTARY MATERIAL

Throughout the supplement, we use commas to separate the photon numbers in different modes, e.g., what in the main text was written as $|0002\rangle$ is written as $|0, 0, 0, 2\rangle$.

Passive Linear Optics Upper Bound for Unambiguous Bell Measurement in Single-Rail

The mathematical formulation presented in Ref. [8] (which dealt with dual-rail Bell measurements with the help of passive linear optics and vacuum ancillae) could also be applied to the case of single-rail Bell measurements. The following argument, however, is not only simpler, but also includes the possibility of conditional dynamics, which was excluded in Ref [8]. We show that in single-rail, passive linear networks aided by an arbitrary number of vacuum modes and conditional dynamics give a tight upper bound of 50% on unambiguous Bell measurement success probability.

Consider the input $|\phi^\pm\rangle \otimes |\xi\rangle$ to a passive linear circuit, where $|\xi\rangle$ is the $(n-2)$ -mode vacuum ancilla, $|0\rangle^{\otimes(n-2)}$. For concreteness, the states $|\phi^\pm\rangle$ are input in modes one and two (this numbering is arbitrary). The effect of an n -mode passive linear circuit is to mix the input creation operators ($a_i^\dagger$), such that the output operators ($b_i^\dagger$) are given by

$$b_i^\dagger = \sum_{j=1}^n U_{ij} a_j^\dagger, \quad (13)$$

where U_{ij} is the (i, j) -element of an $n \times n$ unitary matrix. This implies that the inputs $|\phi^\pm\rangle \otimes |\xi\rangle$ are mapped to

$$|\phi^\pm\rangle \otimes |\xi\rangle \rightarrow \frac{1}{\sqrt{2}} (1 \pm \sum_{i,j=1}^n U_{1i} a_i^\dagger U_{2j} a_j^\dagger) |0\rangle^{\otimes n}. \quad (14)$$

In the above form, it is readily seen that for a static network, the photon-number patterns in the output are identical for $|\phi^+\rangle$ and $|\phi^-\rangle$. In fact, the patterns are identical even after allowing for conditional dynamics. To see this, consider the cases of detecting zero, one or two photons in some mode s . If we detect two photons in s , then the rest of the modes contain the vacuum, which is indistinguishable for the two inputs. Now, say we detect one photon in s . Then the conditional state is

$$|\phi^\pm\rangle \otimes |\xi\rangle \rightarrow \sim \pm \sum_k \alpha_k a_k^\dagger |0\rangle^{\otimes(n-1)}, \quad (15)$$

where the summation over k runs from mode one to $(s-1)$ and from $(s+1)$ to n , and α_k are some undetermined coefficients. Again, the output patterns are identical for the inputs even after further linear processing. To see that the case of zero photons in s is also a failure event, notice that after detecting zero photons, the conditional state looks similar to that in Eq. (14), except that the conditional state is over $n-1$ modes instead of n . This implies, once again, that any further linear processing would be futile. Hence, the probability of discriminating between the states $|\phi^\pm\rangle$ is zero. Combined with the fact that a balanced beam splitter deterministically discriminates between the two states $|\psi^\pm\rangle$, we arrive at the tight upper bound of 50% success probability for SR BM using a passive linear-optical circuit, an arbitrary number of vacuum modes and conditional dynamics.

Complete Output in the Dual-Rail Case

Using Eqs. (3), we can write the effect of the squeezing operator on the states $|0\rangle$ and $|2\rangle$ as

$$\begin{aligned} \mathcal{S}|0\rangle &= \sqrt{\text{sech } r} \sum_{n=0}^{\infty} \frac{\sqrt{2n!}}{n!} \left(\frac{-\tanh r}{2} \right)^n |2n\rangle, \\ \mathcal{S}|2\rangle &= \frac{\sqrt{\text{sech } r} \tanh r}{\sqrt{2}} \sum_{n=0}^{\infty} \frac{\sqrt{2n!}}{n!} \left(\frac{-\tanh r}{2} \right)^n |2n\rangle + \text{sech}^{5/2} r \sum_{n=1}^{\infty} \left(\frac{-\tanh r}{2} \right)^{n-1} \frac{\sqrt{2n!}}{\sqrt{2}(n-1)!} |2n\rangle. \end{aligned}$$

The next step is to apply the squeezing operator on the states $|\phi^\pm\rangle$ as given in Eqs. (2):

$$\begin{aligned}
|\phi^\pm\rangle \rightarrow & \frac{\tanh r}{\sqrt{2}} \operatorname{sech}^2 r \sum_{\substack{m=0, n=0 \\ p=0, q=0}}^{\infty} \frac{\sqrt{(2m)!(2n)!(2p)!(2q)!}}{m!n!p!q!} \left(\frac{-\tanh r}{2}\right)^{m+n+p+q} (1 \pm 1) |2m, 2n, 2p, 2q\rangle \\
& + \frac{\operatorname{sech}^4 r}{2} \sum_{p=0, q=0}^{\infty} \frac{\sqrt{(2p)!(2q)!}}{p!q!} \left(\frac{-\tanh r}{2}\right)^{p+q} \\
& \times \left(\sum_{m=1, n=0}^{\infty} \left(\frac{-\tanh r}{2}\right)^{m+n-1} \frac{\sqrt{(2m)!(2n)!}}{\sqrt{2}(m-1)!n!} |2m, 2n, 2p, 2q\rangle \pm \sum_{m=0, n=1}^{\infty} \frac{\sqrt{(2m)!(2n)!}}{\sqrt{2}m!(n-1)!} \left(\frac{-\tanh r}{2}\right)^{m+n-1} |2m, 2n, 2p, 2q\rangle \right) \\
& + \frac{\operatorname{sech}^4 r}{2} \sum_{m=0, n=0}^{\infty} \frac{\sqrt{(2m)!(2n)!}}{m!n!} \left(\frac{-\tanh r}{2}\right)^{m+n} \\
& \times \left(\sum_{p=0, q=1}^{\infty} \left(\frac{-\tanh r}{2}\right)^{p+q-1} \frac{\sqrt{(2p)!(2q)!}}{\sqrt{2}p!(q-1)!} |2m, 2n, 2p, 2q\rangle \pm \sum_{p=1, q=0}^{\infty} \left(\frac{-\tanh r}{2}\right)^{p+q-1} \frac{\sqrt{(2p)!(2q)!}}{\sqrt{2}q!(p-1)!} |2m, 2n, 2p, 2q\rangle \right).
\end{aligned}$$

Next, we want to identify the output based on the number of photons in each mode. Since this requires forming linear combinations of the above summations, the coefficients of the terms turn out to be similar with minor differences in relative signs. Hence, in order to write the complete output compactly, we define the functions $g^\pm$, $h^\pm$, $j^\pm$ and $k^\pm$ with generic mathematical operations ($\&_1$, $\&_2$, $\&_3$ and $\&_4$) as follows:

$$g^\pm(m, \&_1) = \frac{\operatorname{sech}^2 r}{2} \frac{\sqrt{(2m)!}}{m!} \left(\frac{-\tanh r}{2}\right)^m (\alpha^\pm \&_1 m\beta), \quad (16a)$$

$$h^\pm(m, n, \&_1, \&_2) = \frac{\operatorname{sech}^2 r}{2} \frac{\sqrt{(2m)!(2n)!}}{m!n!} \left(\frac{-\tanh r}{2}\right)^{m+n} (\alpha^\pm \&_1 m\beta \&_2 n\beta), \quad (16b)$$

$$j^\pm(m, n, p, \&_1, \&_2, \&_3) = \frac{\operatorname{sech}^2 r}{2} \frac{\sqrt{(2m)!(2n)!(2p)!}}{m!n!p!} \left(\frac{-\tanh r}{2}\right)^{m+n+p} (\alpha^\pm \&_1 m\beta \&_2 n\beta \&_3 p\beta), \quad (16c)$$

$$k^\pm(m, n, p, q, \&_1, \&_2, \&_3, \&_4) = \frac{\operatorname{sech}^2 r}{2} \frac{\sqrt{(2m)!(2n)!(2p)!(2q)!}}{m!n!p!q!} \left(\frac{-\tanh r}{2}\right)^{m+n+p+q} (\alpha^\pm \&_1 m\beta \&_2 n\beta \&_3 p\beta \&_4 q\beta), \quad (16d)$$

where $\alpha^\pm = \sqrt{2} \tanh r (1 \pm 1)$ and $\beta = -\sqrt{2} \operatorname{sech}^2 r / \tanh r$ (note that we have defined $\alpha^\pm$ slightly differently here compared to Eq. (4) in order to highlight the exponentially decaying factor of $\operatorname{sech}^2 r$ with each coefficient). Using these functions we can write the output from the linear network as:

$$\begin{aligned}
|\phi^\pm\rangle \rightarrow & \frac{\operatorname{sech}^2 r}{2} \alpha^\pm |0, 0, 0, 0\rangle + \sum_m^\infty [g^\pm(m, +)(|2m, 0, 0, 0\rangle + |0, 0, 0, 2m\rangle) + g^\pm(m, \pm)(|0, 2m, 0, 0\rangle + |0, 0, 2m, 0\rangle)] \\
& + \sum_{m, n}^\infty [h^\pm(m, n, +, \pm)(|2m, 2n, 0, 0\rangle + |2m, 0, 2n, 0\rangle) + h^\pm(m, n, +, +)|2m, 0, 0, 2n\rangle + h^\pm(m, n, \pm, \pm)|0, 2m, 2n, 0\rangle \\
& + h^\pm(m, n, \pm, +)(|0, 2m, 0, 2n\rangle + |0, 0, 2m, 2n\rangle)] + \sum_{m, n, p}^\infty [j^\pm(m, n, p, \pm, \pm, +)|0, 2m, 2n, 2p\rangle + j^\pm(m, n, p, +, \pm, \pm)|2m, 2n, 2p, 0\rangle \\
& + j^\pm(m, n, p, +, \pm, +)(|2m, 0, 2n, 2p\rangle + |2m, 2n, 0, 2p\rangle)] + \sum_{m, n, p, q}^\infty k^\pm(m, n, p, q, +, \pm, \pm, +)|2m, 2n, 2p, 2q\rangle, \quad (17)
\end{aligned}$$

where all the lower limits on the summations start from one. Two-photon terms are made unambiguous by setting their coefficients equal to zero for $|\phi^+\rangle$ input, i.e., by setting $g^+(1, +) = 0$ (or equivalently $\alpha^+ + \beta = 0$). Higher order distinguishable terms can be enumerated by noticing that some of the coefficients $h^-(m, n, \&_1, \&_2)$, $j^-(m, n, p, \&_1, \&_2, \&_3)$ and $k^-(m, n, p, q, \&_1, \&_2, \&_3, \&_4)$ in Eqs. (16) and (17) can be made zero for suitable values of m , n , p and q . This is succinctly presented in Table [II]:

Evaluating all the unambiguous terms that give up to 0.01% contribution to the success probability, we arrive at a probability of 37.49% for $|\phi^+\rangle$ and 19.75% for $|\phi^-\rangle$, giving us an overall success probability of 64.3%.

TABLE II: Higher Order Unambiguous Terms in $|\phi^+\rangle$

Condition	Unambiguous Terms in $ \phi^+\rangle$
$m = n$	$ 2m, 2n, 0, 0\rangle, 2m, 0, 2n, 0\rangle, 0, 2m, 0, 2n\rangle, 0, 0, 2m, 2n\rangle$
$m - n + p = 0$	$ 2m, 0, 2n, 2p\rangle, 2m, 2n, 0, 2p\rangle$
$m - n - p = 0$	$ 2m, 2n, 2p, 0\rangle$
$m - n - p + q = 0$	$ 2m, 2n, 2p, 2q\rangle$

Complete Output in the Single-Rail, Equal Squeezing Case

For the case of equal squeezing, the complete $|\phi^\pm\rangle$ output can be written as:

$$\begin{aligned}
|\phi^\pm\rangle \rightarrow & \frac{\text{sech } r}{\sqrt{2}} \left(|0, 0\rangle + \sum_n \left(\frac{-\tanh r}{2} \right)^{n-1} \frac{\sqrt{(2n)!}}{2n(n-1)!} ((-\tanh r \mp n \text{sech}^2 r) |2n, 0\rangle + (-\tanh r \pm n \text{sech}^2 r) |0, 2n\rangle) \right) \\
& + \frac{\text{sech } r}{\sqrt{2}} \left(\sum_{m,n} \left(\frac{-\tanh r}{2} \right)^{m+n-1} \frac{\sqrt{(2m)!(2n)!}}{2 m!n!} (-\tanh r \pm m \text{sech}^2 r \mp n \text{sech}^2 r) |2n, 2m\rangle \right), \quad (18)
\end{aligned}$$

where the lower limit on the summations again starts from one. To set the coefficient of the $|02\rangle$ term equal to zero for $|\phi^+\rangle$ input, we must satisfy the condition $-\tanh r + \text{sech}^2 r = 0$, which implies $r = 0.7218$ (a squeezing of 6.2696 dB). This condition is also fulfilled for higher photon-number states of the form $|2n, 2m\rangle$ whenever $m - n = \pm 1$. For example, the states $|2, 4\rangle$ and $|4, 6\rangle$ unambiguously distinguish $|\phi^+\rangle$ with a probability of 1.2% and 0.1%, respectively. Similarly, by symmetry of the above equation, the states $|4, 2\rangle$ and $|6, 4\rangle$ unambiguously distinguish $|\phi^-\rangle$ with a probability of 1.2% and 0.1%, respectively. Adding up the contributions from all the terms that give at least 0.01% success probability gives us an overall probability of 62.5%.

Numerical Calculations for the Single-Rail Case

Numerical calculations on a two-mode network with real parameters were done in Mathematica (the code is available upon request). Quantum Mathematica add-on by Jose Luis Gómez-Muñoz and Francisco Delgado was used for part of the simulation, which is available at <http://homepage.cem.itesm.mx/lgoomez/quantum/>. The objective was to see if the success probability of 62.5% in SR is optimal within the context of a two-mode network characterized by real parameters in the Bloch-Messiah Reduction.

Eqs. (7) and (9) were used to numerically evaluate the success probability. We swept θ_1 in steps of 0.01π radians, and the unit-less parameters r_1 and r_2 in steps of 0.05 from 0 to 1 (for a maximum squeezing of 8.686 dB). θ_2 was constrained by one of the four conditions $\Omega^+ = 0$, $\Omega^- = 0$, $\omega^+ = 0$ or $\omega^- = 0$. Bell states were simulated to have up to 26 photons in each mode (implying an error of less than 1% from neglected terms in the success probability at a squeezing of 8.6859 dB). An output that was 400 times more likely to occur for an input state $|A\rangle$ than for any other input was considered to unambiguously identify $|A\rangle$.

Calculating the success probability for a total of 352,800 numerical data points, it was found that, within a numerical accuracy of 1%, the optimal success probability was 62.5%, which happens for equal squeezing in the two arms of the network between 6.08 dB and 6.51 dB. This is shown in Fig. [3] where we plot the success probability as a function of squeezing and θ_1 for equal squeezing in the two arms (θ_2 stays constrained by the condition $\Omega^+ = 0$).

In Fig. [4], we present success probability plots as a function of squeezing in the two arms of the linear network for randomly chosen values of $\theta_1 = 0, 0.67\pi, 1.35\pi$ and 1.8π radians. These plots are all for the data set constrained by the condition $\Omega^+ = 0$ (the other three conditions produce similar plots). We would like to point out that the plots are not symmetric in the squeezing of the modes, since the coefficients given in Eq. (10) are not symmetric in r_1 and r_2 . As can be seen from the plots, qualitatively, the peak value of the success probability is about 60%. This can be quantitatively corroborated by looking at the success probability of individual data points. Since the plots do not add much to an intuitive understanding of the interplay between active and passive linear optics, we did not consider it worthwhile adding plots for other values of θ_1 . It is unlikely that generalizing the numerical calculations to include phase shifts in an arbitrary two-mode linear network will change the upper bound, though this will have to be addressed in future work.

FIG. 3: Success probability (P) for $r_1 = r_2$. θ_2 is constrained by $\Omega^+ = 0$. P is bounded from below by 50% since the states $|\phi^\pm\rangle$ are deterministically distinguishable for $r_1 = r_2$. Since θ_2 is constrained, every value of θ_1 gives a success probability of 62.5% at a squeezing of 6.2696 dB.

FIG. 4: Success probability as a function of r_1 and r_2 for various values of θ_1 after imposing the condition $\Omega^+ = 0$. S_1 and S_2 stand for squeezing in modes one and two of the two-mode network, respectively. For every value of θ_1 we see a peak in the discrimination success probability for equal squeezing in the two modes of around 6 dB, as expected from the analytical calculation of the equal squeezing case presented in the main text.
